## Abstract

We study several statistically and biologically motivated learning rules using the same visual environment, one made up of natural scenes, and the same single cell neuronal architecture. This allows us to concentrate on the feature extraction and neuronal coding properties of these rules. Included in these rules are kurtosis and skewness maximization, the quadratic form of the BCM learning rule, and single cell ICA. Using a structure removal method, we demonstrate that receptive fields developed using these rules depend on a small portion of the distribution. We find that the quadratic form of the BCM rule behaves in a manner similar to a kurtosis maximization rule when the distribution contains kurtotic directions, although the BCM modification equations are computationally simpler.

# 1 Introduction

Recently several learning rules that develop simple cell-like receptive fields in a natural image environment have been proposed (Law and Cooper, 1994; Olshausen and Field, 1996; Bell and Sejnowski, 1997). The details of these rules are different as well as their computational reasoning, however they all depend on statistics of order higher than two and they all produce sparse distributions.

In a sparse distribution most of the mass of the distribution is concentrated around zero, and the rest of the distribution extends much farther out. In other words, a neuron that has sparse response, responds strongly to a small subset of patterns in the input environment and weakly to all others. Bi-modal and exponential distributions are examples of sparse distributions, whereas Gaussian and uniform distributions are not considered sparse. It is known that natural images produce long-tailed, or exponential, distributions (Daugman, 1988; Field, 1994). It has further been argued that local linear transformations such as Gabor filters or center-surround produce exponential-tailed histogram (Ruderman, 1994). Reasons given vary from the specific arrangements of the Fourier phases of natural images (Field, 1994) to the existence of edges. Since the exponential distribution is optimal from the view point of information theory under the assumption of positive and fixed average activity (Ruderman, 1994; Levy and Baxter, 1996; Intrator, 1996), it is a natural candidate for detailed study in conjunction with neuronal learning rules.

In what follows we investigate several specific modification functions that have the general properties of BCM synaptic modification functions (Bienenstock et al., 1982), and study their feature extraction properties in a natural scene environment. BCM synaptic modification functions are characterized by a negative region for small post-synaptic depolarization, a positive region for large post-synaptic depolarization, and a threshold which moves and switches between the Hebbian and anti-Hebbian regions. Several of the rules we consider are derived from standard statistical measures (Kendall and Stuart, 1977), such as skewness and kurtosis, based on polynomial moments. We compare these with the quadratic form of BCM (Intrator and Cooper, 1992), though one should note that this is not the only form that could be used. By subjecting all of the learning rules to the same input statistics and retina/LGN preprocessing and by studying in detail the single neuron case, we eliminate possible network/lateral interaction effects and can examine the properties of the learning rules themselves.

We start with a motivation for the learning rules used in this study, and then present the initial results. We then explore some of the similarities and differences between the rules and the receptive fields they form. Finally, we introduce a procedure for directly measuring the sparsity of the representation a neuron learns; this gives us another way to compare the learning rules, and a more quantitative measure of the concept of sparse representations.

## 2 Motivation

We use two methods for motivating the use of the particular rules. One comes from Projection Pursuit (Friedman, 1987), where we use an energy function to find directions where the projections of the data are non-Gaussian (Huber, 1985, for review); the other is Independent Component Analysis (Comon, 1994), where one seeks directions where the projections are statistically independent. These methods are related, as we shall see, but they provide two different approaches for the current work.

### 2.1 Exploratory projection pursuit and feature extraction

Diaconis and Freedman (1984) show that for most high-dimensional clouds (of points), most low-dimensional projections are approximately Gaussian. This finding suggests that important information in the data is conveyed in those directions whose single dimensional projected distribution is far from Gaussian. There is, however, some indication (Zetsche, 1997) that for natural images, random local projections yield somewhat longer tailed distributions than Gaussian. We can still justify this approach, because interesting structure can still be found in *non-random directions* which yield projections that are farther from Gaussian.

Intrator (1990) has shown that a BCM neuron can find structure in the input distribution that exhibits deviation from Gaussian distribution in the form of multi-modality in the projected distributions. This type of deviation, which is measured by the first three moments of the distribution, is particularly useful for finding clusters in high dimensional data through the search for multi-modality in the *projected distribution* rather than in the original high dimensional space. It is thus useful for classification or recognition tasks. In the natural scene

environment, however, the structure does not seem to be contained in clusters. In this work we show that the BCM neuron can still find interesting structure in non-clustered data.

The most common measures for deviation from Gaussian distribution are skewness and kurtosis which are functions of the first three and four moments of the distribution respectively. Rules based on these statistical measures satisfy the BCM conditions proposed in Bienenstock et al. (1982), including a threshold-based stabilization. The details of these rules and some of the qualitative features of the stabilization are different, however. Some of these differences are seemingly important, while others seem not to affect the results significantly. In addition, there are some learning rules, such as the ICA rule of Bell and Sejnowski (1997) and the sparse coding algorithm of Olshausen and Field (1995), which have been used with natural scene inputs to produce oriented receptive fields. We do not include these in our comparison because the learning is not based on the activity and weights of a *single neuron*, and thus detract from our immediate goal of comparing rules with the same input structure and neuronal architecture.

## 2.2 Independent Component Analysis

Recently it has been claimed that the independent components of natural scenes are the edges found in simple cells (Bell and Sejnowski, 1997). This was achieved through the maximization of the mutual entropy of a set of mixed signals. Others (Hyvarinen and Oja, 1997) have claimed that maximizing kurtosis, with the proper constraints, can also lead to the separation of mixed signals into independent components. This alternate connection between kurtosis and receptive fields leads us into a discussion of ICA.

Independent Component Analysis (ICA) is a statistical signal processing technique whose goal is to express a set of random variables as linear combinations of statistically independent variables. We observe  $k$  scalar variables  $(d_1, d_2, \dots, d_k)^T \equiv \mathbf{d}$  which are assumed to be linear combinations of  $n$  unknown *statistically independent* variables  $(s_1, s_2, \dots, s_n)^T$ . We can express this mixing of the sources  $\mathbf{s}$  as

$$\mathbf{d} = \mathbf{A}\mathbf{s} \tag{2.1}$$

where  $\mathbf{A}$  is an unknown  $k \times n$  mixing matrix. The problem of ICA is then to estimate both the mixing matrix  $\mathbf{A}$  and the sources  $\mathbf{s}$  using only the observation of the mixtures  $\mathbf{d}_i$ . Using the feature extraction properties of ICA, the columns of  $\mathbf{A}$  represent features, and  $s_i$  represent the amplitude of each feature in the observed mixtures  $\mathbf{d}$ . These are the features in which we are interested.

In order to perform ICA, we first make a linear transformation of the observed mixtures

$$\mathbf{c} = \mathbf{M}\mathbf{d} \quad (2.2)$$

These linearly transformed variables would be the outputs of the neurons, in a neural network implementation and  $\mathbf{M}$ , the unmixing matrix or matrix of features, would be the weights. Two recent methods for performing ICA (Bell and Sejnowski, 1995; Amari et al., 1996) involve maximizing the entropy of the transformed mixtures,  $\mathbf{c}$ , and minimizing the mutual information of  $\mathbf{c}$  with respect to the transformation matrix,  $\mathbf{M}$ , so that the components of  $\mathbf{c}$  are independent. These methods are, by their definition, multi-neuron algorithms and therefore do not fit well into the framework of this study.

The search for independent components relies on the fact that a linear mixture of two non-Gaussian distributions will become more Gaussian than either of them. Thus, by seeking projections  $c = (\mathbf{d} \cdot \mathbf{m})$  which maximize deviations from Gaussian distribution, we recover the original (independent) signals. This explains the connection of ICA to the framework of exploratory projection pursuit (Friedman and Tukey, 1974; Friedman, 1987). In particular it holds for the kurtosis projection index, since a linear mixture will be less kurtotic than its original components.

Kurtosis and skewness, have also been used for ICA as approximations of the negative entropy (Jones and Sibson, 1987). It remains to be seen if the basic assumption used in ICA, that the signals are made up of independent sources, is valid. The fact that different ICA algorithms, such as kurtosis and skewness maximization, yield different receptive fields could be an indication that the assumption is not completely valid.

### 3 Synaptic modification rules

In this section we outline the derivation for the learning rules in this study, using either the method from projection pursuit or independent component analysis. Neural activity is assumed to be a positive quantity, so for biological plausibility we denote by  $c$  the rectified activity  $\sigma(\mathbf{d} \cdot \mathbf{m})$  and assume that the sigmoid is a smooth monotone function with a positive output (a slight negative output is also allowed).  $\sigma'$  denotes the derivative of the sigmoidal. The rectification is required for all rules that depend on odd moments because these vanish in a symmetric distribution such as natural scenes. We also demonstrate later that the rectification makes little difference on learning rules that depend on even moments.

We study the following measures:

**Skewness 1** This measures the deviation from symmetry (Kendall and Stuart, 1977, for review) and is of the form:

$$S_1 = E[c^3]/E^{1.5}[c^2]. \quad (3.3)$$

A maximization of this measure via gradient ascent gives

$$\nabla S_1 = \frac{1}{\Theta_M^{1.5}} E [c (c - E[c^3]/E[c^2]) \sigma' \mathbf{d}] = \frac{1}{\Theta_M^{1.5}} E [c (c - E[c^3]/\Theta_M) \sigma' \mathbf{d}] \quad (3.4)$$

where  $\Theta_m$  is defined as  $E[c^2]$ .

**Skewness 2** Another skewness measure is given by

$$S_2 = E[c^3] - E^{1.5}[c^2]. \quad (3.5)$$

This measure requires a stabilization mechanism, because it is not invariant under constant multiples of the activity  $c$ . We stabilize the rule by requiring that the vector of weights, which is denoted by  $\mathbf{m}$ , has a fixed norm,

say  $\|\mathbf{m}\| = 1$ . The gradient of this measure is

$$\nabla S_2 = 3E \left[ c^2 - c\sqrt{E[c^2]} \right] = 3E \left[ c \left( c - \sqrt{\Theta_M} \right) \sigma' \mathbf{d} \right], \quad (3.6)$$

subject to the constraint  $\|\mathbf{m}\| = 1$ .

**Kurtosis 1** Kurtosis measures deviation from Gaussian distribution mainly in the tails of the distribution. It has the form

$$K_1 = E[c^4]/E^2[c^2] - 3. \quad (3.7)$$

This measure has a gradient of the form

$$\nabla K_1 = \frac{1}{\Theta_M^2} E \left[ c \left( c^2 - E[c^4]/E[c^2] \right) \sigma' \mathbf{d} \right] = \frac{1}{\Theta_M^2} E \left[ c \left( c^2 - E[c^4]/\Theta_M \right) \sigma' \mathbf{d} \right]. \quad (3.8)$$

**Kurtosis 2** As before, there is a similar form which requires some stabilization:

$$K_2 = E[c^4] - 3E^2[c^2]. \quad (3.9)$$

This measure has a gradient of the form

$$\nabla K_2 = 4E \left[ c^3 - cE[c^2] \right] = 3E \left[ c(c^2 - \Theta_M) \sigma' \mathbf{d} \right], \quad \|\mathbf{m}\| = 1. \quad (3.10)$$

In all the above, the maximization of the measure can be used as a goal for projection seeking. The variable  $c$  can be thought of as a (nonlinear) projection of the input distribution onto a certain vector of weights, and the maximization then defines a learning rule for this vector of weights. The multiplicative forms of both kurtosis and skewness do not require an extra stabilization constraint.

**Kurtosis 2 and ICA** It has been shown (Hyvarinen and Oja, 1996) that kurtosis, defined as

$$K_2 = E[c^4] - 3E^2[c^2]$$

can be used for ICA. This can be seen by using the property of this kurtosis measure,  $K_2(x_1 + x_2) = K_2(x_1) + K_2(x_2)$  for independent variables, and defining  $\mathbf{z} = \mathbf{A}^T \mathbf{m}$ . We then get

$$K_2(\mathbf{m} \cdot \mathbf{d}) \equiv K_2(\mathbf{m}^T \mathbf{d}) = K_2(\mathbf{m}^T \mathbf{A} \mathbf{s}) = K_2(\mathbf{z}^T \mathbf{s}) = \sum_{j=1}^n z_j^4 K_2(s_j) \quad (3.11)$$

The extremal points of Equation 3.11 with respect to  $\mathbf{z}$  under the constraint  $E[(\mathbf{m} \cdot \mathbf{d})^2]$  occur when one component  $z_j$  of  $\mathbf{z}$  is  $\pm 1$  and all the rest are zero (Delfosse and Loubaton, 1995). In other words, finding the extremal points of kurtosis leads to projections where  $\mathbf{m} \cdot \mathbf{d} \equiv \mathbf{m}^T \mathbf{d} = \mathbf{z}^T \mathbf{s}$  equals, up to a sign, a single component  $s_j$  of  $\mathbf{s}$ . Thus, finding the extrema of kurtosis of the projections enables the estimation of the independent components *individually*, rather than all at once, as is done by other ICA rules. A full ICA code could be developed by introducing a lateral inhibition network, for example, but we restrict ourselves to the single neuron case here for simplicity.

Maximizing  $K_2$  under the constraint  $E[(\mathbf{m} \cdot \mathbf{d})^2]$ , and defining the covariance matrix of the inputs  $\mathbf{C} = E[\mathbf{d} \mathbf{d}^T]$ , yields the following learning rule

$$\mathbf{m} = \frac{2}{\lambda} (\mathbf{C}^{-1} E[\mathbf{d}(\mathbf{m} \cdot \mathbf{d})^3] - 3\mathbf{m}). \quad (3.12)$$

This equation leads to an iterative “fixed-point algorithm”, which converges very quickly and works both for single cell and network implementations.

**Quadratic BCM** The Quadratic BCM (QBCM) measure as given in (Intrator and Cooper, 1992) is of the form

$$\text{QBCM} = \frac{1}{3} E[c^3] - \frac{1}{4} E^2[c^2]. \quad (3.13)$$

Maximizing this form using gradient ascent gives the learning rule:

$$\nabla \text{QBCM} = E [c^2 - cE[c^2]] = E[c(c - \Theta_M)\sigma' \mathbf{d}]. \quad (3.14)$$

Unlike the measures  $S_2$  and  $K_2$  above, the Quadratic BCM rule does not require any additional stabilization. This turns out to be an important property, since additional information can then be transmitted using the resulting norm of the weight vector  $m$  (Intrator, 1996).

## 4 Methods

We use 13x13 circular patches from 12 images of natural scenes as the visual environment. Two different types of preprocessing of the images are used for each of the learning rules. The first is a Difference of Gaussians (DOG) filter, which is commonly used to model the processing done in the retina (Law and Cooper, 1994). The second is a whitening filter, used to eliminate the second order correlations (Oja, 1995; Bell and Sejnowski, 1995). Whitening the data in this way allows one to use learning rules which are dependent on higher moments of the data, but are particularly sensitive to the second moment.

At each iteration of the learning, a patch is taken from the preprocessed (either DOGED or whitened) images and presented to the neuron. The moments of the output,  $c$ , are calculated iteratively using

$$E[c^n(t)] = \frac{1}{\tau} \int_{-\infty}^t c^n(t') e^{-(t-t')/\tau} dt'$$

In the cases where the learning rule is under-constrained (i.e.  $K_2$  and  $S_2$ ) we also normalize the weights at each iteration.

For Oja's fixed-point algorithm, the learning was done in batches of 1000 patterns over which the expectation values were performed. However, the covariance matrix was calculated over the entire set of input patterns.

## 5 Results

### 5.1 Receptive Fields

The resulting receptive fields (RFs) formed are shown in Figures 1 and 2 for both the DOGED and whitened images, respectively. Each RF shown was achieved using different random initial conditions for the weights. Every learning rule developed oriented receptive fields, though some were more sensitive to the preprocessing than others. The additive versions of kurtosis and skewness,  $K_2$  and  $S_2$  respectively, developed significantly different RFs in the whitened environment compared with the DOGED environment. The RFs in the whitened environment had higher spatial frequency and sampled from more orientations than the RFs in the DOGED environment. This behavior, as well as the resemblance of the receptive fields in the DOGED environment to those obtained from PCA (Shouval and Liu, 1996), suggest that these measures have a strong dependence on the second moment.

The multiplicative versions of kurtosis and skewness,  $K_1$  and  $S_1$  respectively, as well as Quadratic BCM, sampled from many orientations regardless of the preprocessing. The multiplicative skewness rule,  $S_1$ , gives receptive fields with lower spatial frequencies than either Quadratic BCM or the multiplicative kurtosis rule. This also disappears with the whitened inputs, which implies that the spatial frequency of the receptive field is related to the strength of the dependence of the learning rule on the second moment. Example receptive fields using Oja's fixed-point ICA algorithm are also shown in Figure 2, and not surprisingly look qualitatively similar to those found using the stochastic maximization of additive kurtosis,  $K_2$ .

The log of the output distributions for all of the rules have the double linear form, which implies a double exponential distribution. This distribution is one which we would consider sparse, but it would be difficult to compare the sparseness of the distributions merely on the appearance of the output distribution alone. In order to determine the sparseness of the code, we introduce a method for measuring it directly.

### Receptive Fields from Natural Scene Input: DOGED

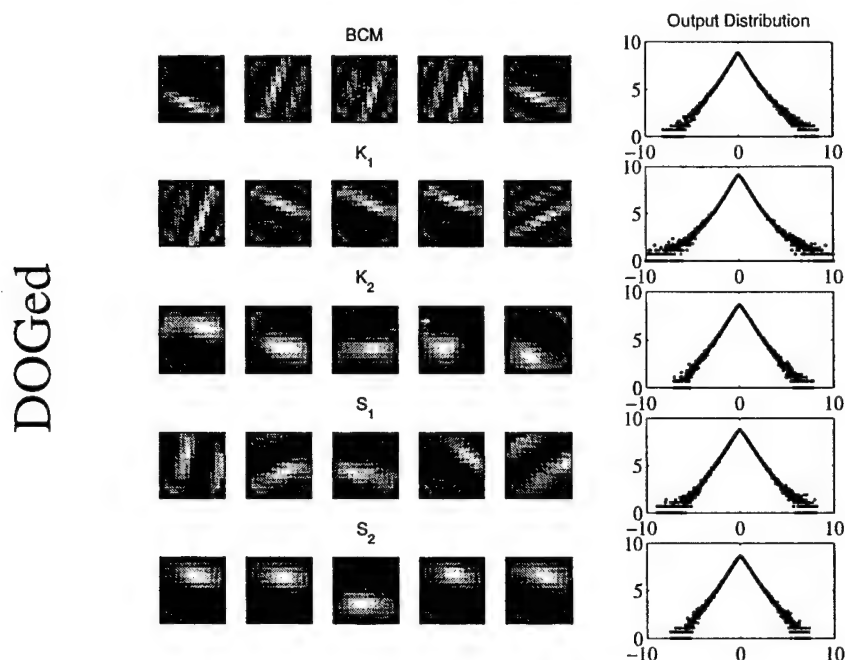

Figure 1: Receptive fields using DOGED image input obtained from learning rules maximizing (from top to bottom) the Quadratic BCM objective function, Kurtosis (multiplicative), Kurtosis (additive), Skewness (multiplicative), and Skewness (additive). Shown are five examples (left to right) from each learning rule as well as the log of the normalized output distribution, before the application of the rectifying sigmoid.

## 5.2 Structure Removal: Sensitivity to Outliers

Learning rules which are dependent on large polynomial moments, such as Quadratic BCM and kurtosis, tend to be sensitive to the tails of the distribution. This property implies that neurons are highly responsive, and sensitive, to the outliers, and consequently leads to a sparse coding of the input signal. One should note that over-sensitivity to outliers is considered to be undesirable in the statistical literature. However, in the case of a sparse code the outliers, or the rare and interesting events, are what is important. The degree to which the neurons form a sparse code determines how much of the input distribution is required for maintaining the RF. This can be done in a straightforward and systematic fashion.

The procedure involves simply eliminating from the environment those patterns for which the neuron responds strongly. An example receptive field and some of the patterns which give that neuron strong responses is shown in Figure 3. These patterns tend to be the high contrast edges, and are thus the structure found in

# Receptive Fields from Natural Scene Input (Whitened)

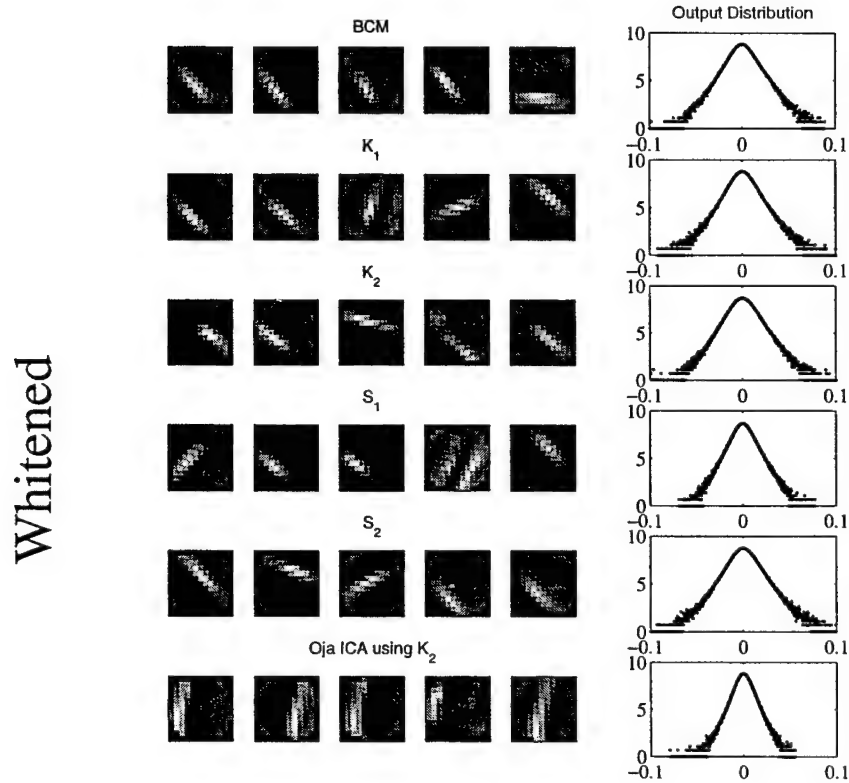

Figure 2: Receptive fields using whitened image input, obtained from learning rules maximizing (from top to bottom) the Quadratic BCM objective function, Kurtosis (multiplicative), Kurtosis (additive), Skew (multiplicative), Skewness (additive), and Oja's ICA rule based on the additive kurtosis measure. Shown are five examples (left to right) from each learning rule as well as the log of the normalized output distribution, before the application of the rectifying sigmoid.

the image. The percentage of patterns that needs to be removed in order to cause a change in the receptive field gives a direct measure of the sparsity of the coding. The process of training a neuron, eliminating patterns which yield high response, and retraining can be done recursively to sequentially remove structure from the input environment, and to pick out the most salient features in the environment. The results of this are shown in Figure 4.

For Quadratic BCM and kurtosis, one need only eliminate *less than one half of a percent* of the input patterns to change the receptive field significantly. The changes which one can observe include orientation, phase and spatial frequency changes. This is a very small percentage of the environment, which suggests that the neuron is coding the information in a very sparse manner. For the skewness maximization rule, more than five percent

Figure 3: Patterns which yield high responses of a model neuron. The example receptive field is shown on the left. Some of the patterns which yield the strongest 1/2 percent of responses are labeled on the image on the right. These patterns are primarily the high contrast edges.

are needed to alter the receptive field properties, which implies a far less sparse coding.

To make this more precise, we introduce a normalized difference measure between two different RFs. If we take two weight vectors,  $\mathbf{m}_1$  and  $\mathbf{m}_2$ , then the normalized difference between them is defined as

$$\mathcal{D} \equiv \frac{1}{4} \left( \frac{\mathbf{m}_1 - \bar{m}_1}{\|\mathbf{m}_1\|} - \frac{\mathbf{m}_2 - \bar{m}_2}{\|\mathbf{m}_2\|} \right)^2 \quad (5.15)$$

$$= \frac{1}{2} (1 - \cos \alpha) \quad (5.16)$$

where  $\alpha$  is the angle between the two vectors, and  $\bar{m}_i$  is the mean of the elements of the vector  $i$ . This measure is not sensitive to scale differences, because the vectors are divided by their norm, and it is not sensitive to scalar offset differences, because the mean of the vectors is subtracted. The measure has a value of zero for identical vectors, and a maximum value of one for orthogonal vectors.

Shown in Figure 5 is the normalized difference as a function of the percentage eliminated, for the different learning rules. Differences can be seen with as little as a tenth of a percent, but only changes of around a half a percent and above are visible as significant orientation, phase, or spatial frequency changes. Although both skewness and Quadratic BCM depend primarily on the third moment, Quadratic BCM behaves more like kurtosis with regards to sparse coding.

When the small, but important, part of the input distribution is eliminated (namely, the tails of the distribution), the neuron seeks a different RF. This occurs in both the BCM and kurtosis learning rules, and most likely occurs in other rules that seek kurtotic projections. It is important to note, however, that patterns must

be eliminated from *both* sides of the distribution for any rule that does not use the rectifying sigmoid because the strong *negative* responses carry as much structure as the strong positive ones. Such responses are not biologically plausible, so they wouldn't be part of the encoding process in real neurons.

It is also interesting to observe that the RF found after structure removal is initially of the same orientation, but of different spatial phase. Once enough input patterns are removed, the RF becomes oriented in a different direction. If the process is continued, all of the orientations and phases would be obtained.

An objection may be made that the receptive fields formed are caused almost entirely by the application of the rectifying sigmoid. For odd powered learning rules, the sigmoid is necessary to obtain oriented receptive fields because the distributions are approximately symmetric. This sigmoid is not needed for rules dependent only on the even powered moments, such as kurtosis. Figure 6 demonstrates that the removal of the sigmoid and the removal of the mean from the moments calculations do not substantially affect the resulting receptive fields of the kurtosis rules.

The choice of 13 by 13 receptive fields was made only for computational efficiency. Figure 7 shows some 21 by 21 receptive fields and it is clear that little difference is made.

Structure Removal for BCM, Kurtosis, and Skew

Figure 4: Receptive fields resulting from structure removal using the Quadratic BCM rule, the rule maximizing the multiplicative form of kurtosis and skewness. The RF on the far left for each rule was obtained in the normal input environment. The next RF to the right was obtained in a reduced input environment, whose patterns were deleted that yielded the strongest 1% of responses from the RF to the left. This process was continued for each RF from left to right, yielding a final removal of about five percent of the input patterns.

Figure 5: Normalized difference between RFs as a function of the percentage deleted in structure removal. The RFs were normalized, and mean zero, in order to neglect magnitude and additive constant changes. The maximum possible value of the difference is 1.

## 6 Discussion

This study attempts to compare several learning rules which have some statistical or biological motivation, or both. For a related study discussing projection pursuit and BCM see (Press and Lee, 1996). We have used natural scenes to gain some more insight about the statistics underlying natural images. There are several outcomes from this study:

- All rules used, found kurtotic distributions. This should not come as a surprise as there are suggestions that a large family of linear filters can find kurtotic distributions (Ruderman, 1994).
- The single cell ICA rule we considered, used the subtractive form of kurtosis as a measure for deviation from Gaussian distributions, achieved receptive fields qualitatively similar to other rules discussed.
- The Quadratic BCM and the multiplicative version of kurtosis are less sensitive to the second moments of the distribution and produce oriented receptive fields even when the data is not whitened. This is clear

from the results about DOG-processed vs. whitened inputs. The reduced sensitivity follows from the built in second order normalization that these rules have, kurtosis via division and BCM via subtraction. The subtractive version of kurtosis is sensitive and produces oriented RF only after sphering the data (Friedman, 1987; Field, 1994).

- Both Quadratic BCM and kurtosis are sensitive to the tails of the distribution. In fact, the RF changes due to elimination of the upper 1/2% portion of the distribution (Figure 4). The change in RF is gradual; at first, removal of some of the inputs results in RFs that have the same orientation but a different phase, once more patterns from the upper portion of the distribution are removed, different RF orientations are found. This finding gives some indication to the kind of inputs the cell is most selective to (values below its highest 99% selectivity), these are inputs with same orientation but with different phase (different locality of RF). The sensitivity to small portions of the distribution represents the other side of the coin of sparse coding. It should be further studied as it may reflect some fundamental instability of the kurtotic approaches.
- The skewness rules can also find oriented RF's. Their sensitivity to the upper parts of the distribution is not so dramatic and thus, the RFs do not change much when few percent of the upper distribution are removed.
- Kurtotic rules can find high kurtosis in either symmetric or rectified distributions. This is not the case for Quadratic BCM rule which requires rectified distributions.
- Quadratic BCM learning rule, which has been advocated as a projection index for finding multi-modality in high dimensional distribution, can find projections emphasizing high kurtosis when no cluster structure is present in the data. We have preliminary indications that the converse is not true, namely, kurtosis measure does not perform well under distributions that are bi- or multi-modal. This will be shown elsewhere.

# Exploring Modifications to the Kurtosis rules

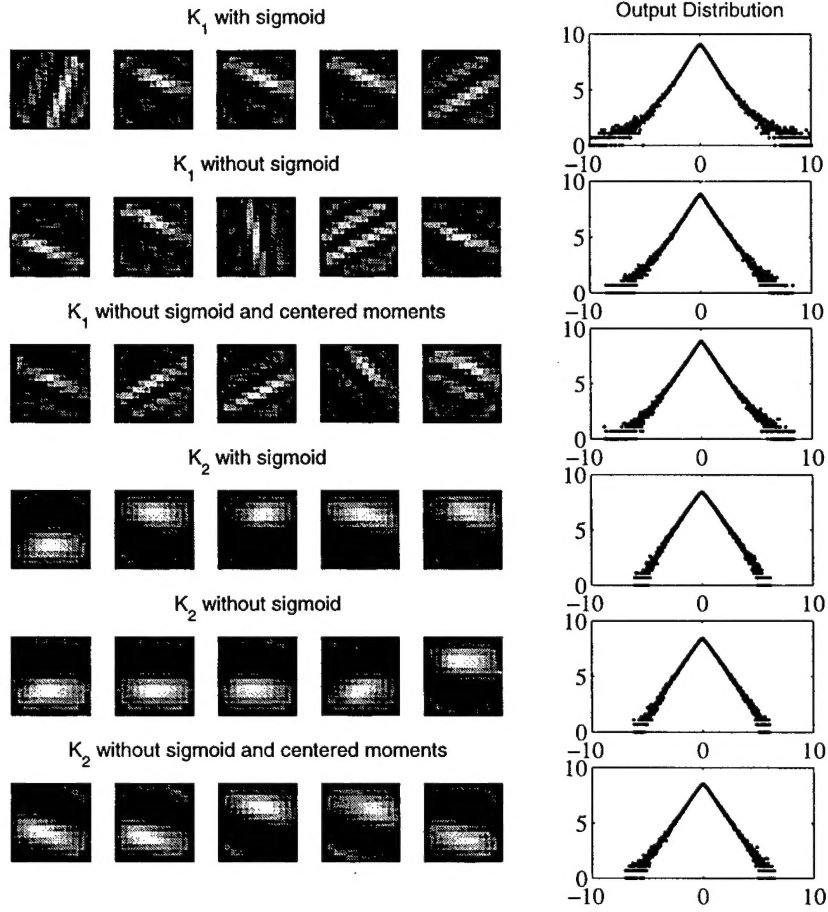

Figure 6: Receptive fields using DOGED image input, obtained from learning rules maximizing (from top to bottom) multiplicative form kurtosis with rectified outputs, non-rectified outputs, and non-rectified outputs with centered moments respectively, and additive form kurtosis with rectified outputs, non-rectified outputs, and non-rectified outputs with centered moments respectively. Shown are five examples (left to right) from each learning rule and the corresponding output distribution.

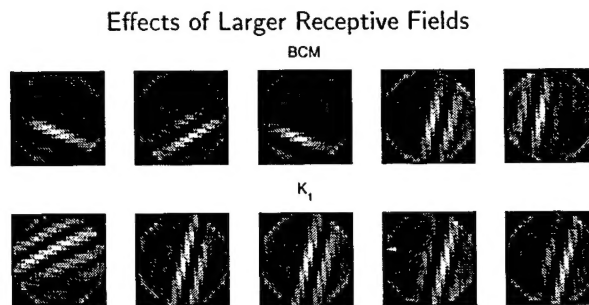

Figure 7: Large receptive fields using DOGED image input, obtained from the Quadratic BCM learning rule and the rule maximizing the multiplicative form of kurtosis.
